Proposal

Abstract

The project proposal is to create a ML model to accurately predict Home Credit Defaults Risks in order to do this we will have to merge several tables and analyze the data using a feature engineering technique with Featuretools module and utilize chart tools as seaborn to present the data and use scikit-learn or keras to get predictions.

Domain Background

Supervised learning is one of the most successfully utilized methods in the machine learning field when it comes to predict future values of many different assets in this case our customer (Home Credit) needs help to predict Home Credit Defaults and with this reduce risk, this will not only help the lender to avoid high risks but also will help their applicant to get unnecessary debt. With the use of Machine Learning tools our customer will reduce the human error at the moment their employees evaluate potential clients.

Problem Statement

The Home Credit Default Risk competition is a supervised classification machine learning task. The objective is to use historical financial and socioeconomic data to predict whether or not an applicant or client will be able to repay the loan. This is a standard supervised classification task:

- Supervised: The labels are included in the training data and the goal is to train a model to learn and predict the labels from the features
- Classification: The label is a binary variable, 0 (will repay loan on time), 1 (will have difficulty repaying the loan)

Dataset

The data is provided by [Home Credit](#), a service dedicated to provide lines of credit to the unbanked population.

There are 7 different data files:

- ✓ Application_train/application_test: the main training and testing data with information about each loan application at Home Credit. Every loan has its own row and is identified by the SK_ID_CURR. The training application data comes from the TARGET with indicating 0: the loan was repaid and 1: the loan was not paid.
- ✓ Bureau: data concerning client's previous credits from other financial institutions. Each previous credit as its own row in the bureau and is identified by the SK_ID_BUREAU, each loan in the application data can have multiple previous credits.
- ✓ Bureau_balance: monthly data about the previous credits in the bureau. Each row is one month of the previous credit, and a single previous credit can have multiple rows, one for each month of the credit length.
- ✓ Previous_application: previous application for loans at Home Credit of clients who have loans in the application data. Each current loan in the application data can have multiple previous loans. Each previous application has one row and is identified by the feature SK_ID_PREV

- ✓ POS_CASH_BALANCE: monthly data about previous points of sale or cash loans clients have had with Home Credit. Each row is one month of a previous point of sale or cash loan, and a single previous loan can have many rows.
- ✓ Credit_card_balance: monthly data about previous cards clients have had with Home Credit. Each row is one month of a credit card balance, and a single credit card can have many rows.
- ✓ Installments_payments: payment history for previous loans at Home Credit. There is one row for every made payment and one row for every missed payment.

Solution Statement

We want to understand the relationship between the 7 datasets and its features, the outcome may sound very straight forward but because we have so many features we can fall in an overfitting problem because of this we may want to analyze the information to see if we need to do some cleanup or even reduce the number of features with tools as PCA. At the moment we consider to implement a classification algorithm and a Neural Network algorithm for the prediction but during the progress of the investigation this might change based on the output.

Benchmark Model

As this is a kaggle [competition](#) a benchmark model would be SK_ID_CURR in the test set, who must predict a probability for the TARGET variable. The submission will be evaluated on area under the ROC curve between the predicted probability and the observed target.

We will run different machine learning algorithms most of them under the classification method and compare their outcome in a ROC curve.

Evaluation Metrics

The model prediction for this problem can be evaluated in several ways and because of this is that will focus only on Risk of paying or not paying the loan based on at least 2 evaluation or prediction models.

Project Design

Because we are predicting a category based on the [scikit-learn map](#) we will follow the classification method first and at least implement one of the different algorithms under the classification umbrella as SGD Classifier or KNN considering that most of data can be numeric but Naïve Bayes is in the picture if there is more text in the data of what we expect.
